

ARMS Performance Module

General design description

ARMS performance module

Summary

ARMS performance module is designed for analyzing portfolios along position groupings and market factor drivers. Standard or custom benchmarks can be used for relative performance measures. An elaborate benchmark handling provides a new dimension to portfolio analysis since it allows for decomposition of the benchmark in the same way as the portfolio. Asset allocation and selection performance according to the popular Brinson-model is available together with more customized ways of splitting performance. Both natural splits such as asset class, instrument type, and risk-factor type as well as custom splits can be presented both from an absolute return and relative return perspective together with risk and stress testing.

In order to provide maximum flexibility in implementation and completeness, both actual portfolio transactions and benchmarks can be imported as real instrument transactions.

A simplified model for importing benchmark data will be available in order to present benchmark returns as comparative index when individual constituents are not available.

Transaction based analysis

ARMS performance module is based on transactions. Transactions can be loaded into ARMS in a transaction specific XML format. Transactions should include information about the position type transacted, the transaction details, and any dynamic portfolio classifications. The purpose of the transaction is to provide information about when it was done and to what terms. Additionally, for other purposes than performance analysis, also settlement information, classifications etc can be provided in the same way as in the current ARMS Position format.

Transactions can be transformed to positions either in a scheduled batch procedure or dynamically in an ARMS desktop client. Server support will be provided to create normalized starting positions and backward position recalculation. Audit trail will be available for back dated transaction altering.

All transactions that comply with the minimum requirements of the XML schema will be available for performance as well as risk analysis.

If detailed bookkeeping transactions can be provided per underlying security and portfolio, correct profit and loss can be calculated at this level. If cash accounting only can be provided on aggregated level the total performance can only be measured on top portfolio level. Current actively performing assets will then be presented without realized flows.

A compact transaction format for exchange traded instruments will be provided but will require an available instrument definition database.

Transaction-based benchmark handling

Handling of benchmark information will mimic the handling of ordinary transactions. This will enable the user to configure benchmarks in a flexible and realistic manner. By monitoring index constituents as actual transactions, it will be possible, ex ante, to include cash positions in order to recreate a total return benchmark from a non-reinvesting index. It is also possible to provide dynamic transactions in a custom index at the same time as real transactions are made.

In the same way as with regular transactions, a hierarchy of portfolios can be created for each fund/client based on benchmark index portfolios. Index portfolios are stored in a standardized stand-alone context. By using a multi-level portfolio benchmark index, it is possible to split the performance attribution analysis on strategic (i.e. asset class) level and tactical level (i.e. instrument level).

Benchmark portfolios can be created using the same type of instruments that can be handled by ARMS for regular portfolios. This means that it is possible to create a custom benchmark index using regular bonds and frn:s as well as indices having total return features with corporate actions such as rights issues and spin-offs.

Performance vs bookkeeping

In measuring performance on a year-to-date or period-to-period basis many choices can be made as to what and how it should be calculated and defined.

ARMS is a typical front-office system in terms of how valuations are done. Given a certain valuation date, ARMS will market value all positions using that day's "market state". Using a strict market valuation concept will have implications for certain type of transactions.

Bonds will be marked to market, or if market quotations are missing, marked to peer group generic curves. (I.e. marked-to-model using generalized market values coming from similar instruments.) This means that current accruals and market price differences will both contribute to performance.

Similarly, a deposit transaction will perform according to its replacement cost i.e. marked to market and not just interest accruals.

For equity related instruments and OTC transactions without intermediate cash-flows the marked-to-market concept will have no material implication how the results can be interpreted.

Total return, realized and unrealized

Portfolio return can be presented at any native level of portfolio and for any period of time. Portfolio performance can further be drilled down to current position level. At the lowest level, performance can be presented as realized and unrealized in the same type of instrument. Provided that information regarding cash reimbursements relating to an instrument type has been provided, realized performance can include such transactions on an "underlying" level.

The screenshot displays the ARMS Limit Client 3.2 pref demo - Quantlab interface. It features a 'Parameters' panel on the left with fields for upload_date (2010-05-25), cust (demo - DemoCust), Hierarchy location, portfolio (GLOBAL), ccy_name (SEK), and from_date (2009-09-01). The main area is divided into two tables: 'Portfolio PnL' and 'Position PnL'.

Portfolio PnL Table:

portfolios	tot_pnl	real_pnl	unreal_pnl	tot_pnl_ytd	real_pnl_ytd	unreal_pnl_ytd

Theoretical and market valuations

Market valuations can be performed in many ways depending on the analysis at hand. ARMS will provide a possibility to value any asset according to a listing of market quoted prices. (I.e. last, mid, bid, ask). Also a pure theoretical valuation will be available in the same way as ARMS prices positions using a stylized set of valuation and risk factors.

Highlighting in the workspace where market prices are not valid is a practical feature.

Portfolio/position splits

A number of pre-defined position splitting levels will be provided for aggregation of performance in absolute and relative terms. Splitting positions commonly together with a certain benchmark comes with a limitation on how many natural split types that the benchmark is loaded with.

Typical natural common (absolute and relative) groups are:

- Currency of position
- Instrument type
- Asset class type
- Derivative vs. spot market instruments
- Underlying instrument classification

Created in Quantlab

Some additional position splits can be provided for both benchmark and portfolio given that the benchmark can be updated with the information for all constituents. For example, rating, sector, country.

In addition to the above natural split types that exist for both actual portfolio as well as for the benchmark, an unlimited number of custom specific position / transaction classifications are available. The custom classifications are position specific and must be provided together with the transactions in a classification XML structure.

Analysis based on custom specific classifications can only be provided in an absolute return context.

Examples of custom classifications are:

- Natural portfolio
- Position strategy
- Economic capital classification
- Accounting headers
- Counterparty

Price/risk factor splits

All risk factors used in ARMS can be individually classified to an unlimited number of classification categories. By default only risk factor class type is defined; (i.e. equity, index, volatility, interest rate, credit spread, commodity, and fx).

All positions will be mapped to one or many of the risk factors available in ARMS. Since also the benchmark constituents will be mapped to the appropriate risk factors (ideally using a 1:1 mapping), a concurrent risk and performance analysis can be performed on the portfolio and benchmark in any of the available risk factor classifications.

Typical custom risk factor classifications are:

- Maturity buckets
- GICS sector classification
- Country
- Exchange trade vs over the counter pricing

Name	Factor PnL	Relative PnL %	Portfolio VaR	Benchmark VaR	Relative VaR

Created in Quantlab

When performance is split on price/risk factors, individual and groups of risk factors do not additively explain the entire performance of a position or portfolio. This is typical for non-linear positions where there are interaction effects on the pricing function between different risk factors. For example, an option has interaction effects between underlying asset price and implied volatility. An additional “Interaction” classification will be introduced in order for the performance to be additive. For risk measures like Value-at-risk which is also a non-additive measure, the interaction factor can also be interpreted as a diversification effect.

Name	Factor PnL	Relative PnL %	Portfolio VaR	Benchmark VaR	Relative VaR

Created in Quantlab

Multi-dimensional splits

Absolute risk and performance can also be calculated and presented in multi-dimensional splits. It is possible to create 2-dimensional position grouping splits and 2-dim factor-position splits. This is especially convenient when working with fixed income products where the combination performance should be explained along the maturity curve.

Server-side calculations

All performance metrics that can be calculated in the client can also be configured to calculate and store in the result database for inclusion on performance reports etc.
